19

20

21 Caribbean *Anolis* lizards exhibit a complex suite of ecological, morphological, and behavioral
22 traits that allow their specialization to particular microhabitats. These microhabitat specialists,
23 called ecomorphs, have independently evolved on the islands of the Greater Antilles, and
24 diversification among anole ecomorphs has been the focus of many studies. Yet, further habitat
25 specialization also occurs among species within the same ecomorph. In this study, we examined
26 ecological, morphological, and behavioral divergence in three Hispaniolan trunk-ground anole
27 species: *Anolis cybotes*, *A. marcanoi*, and *A. longitibialis*. We examined relationships among
28 limb morphology, locomotor behavior, and perch use, and between sexual size dimorphism (a
29 measure for the strength of sexual selection) and sexually-selected morphological traits and
30 behaviors. We found significant differences among the three cybotoid species that mirror
31 differences among the ecomorphs. Across anoles and within cybotoids, species that have longer
32 limbs tend to move less frequently, occupy broader perches, and have smaller fourth toes with
33 fewer lamellae. In addition, species that have high male-biased size dimorphism have larger
34 heads, smaller dewlaps, and smaller testes. These results are consistent with the predictions of
35 sexual selection theory, in that species with large male body size may have larger heads due to
36 increased male-male combat, and smaller testes due to a trade-off between pre- and
37 postcopulatory selection. Overall, this study suggests that a combination of local adaptation and
38 sexual selection produce ecomorphological diversification within cybotoid anoles of the same
39 ecomorph group.

40 Ecomorphology, the study of the relationships between an organism's ecology and its
41 morphology, has revealed that evolution often shapes complex suites of traits to allow
42 specialization to a particular environment. The evolution of such phenotypic suites has facilitated
43 divergence into diverse habitats, driving adaptive radiations in multiple taxa (reviewed in
44 Schluter, 2000). Further, in some groups, ecomorphological evolution has produced strikingly
45 repeatable results, producing discrete types of species adapted to a set of niches (e.g.,
46 *Eleutherodactylus* frogs: Hedges, 1989; *Anolis* lizards: Losos et al., 1998; cichlid fish: Danley
47 and Kocher, 2001; boas and pythons: Esquerré and Keogh, 2016). When habitat specialization in
48 multiple, independent lineages results in the convergent evolution of ecology, morphology, and
49 behavior, the resulting types are termed "ecomorphs" (following Williams, 1972), defined as
50 specialists to a particular microhabitat. While the evolution of ecomorphs has been a focus of
51 macroevolutionary studies, divergence *within* an ecomorph, which can result in further habitat
52 specialization (Losos, 1996), has received far less attention.

53 Of the approximately 150 species of anole lizards (genus *Anolis*) in the Caribbean, most
54 are categorized as one of six ecomorphs: trunk-ground, trunk-crown, trunk, grass-bush, twig, and
55 crown giant (Williams, 1972, 1983; Losos, 2009). Specific ecomorphs have independently
56 evolved on each of the islands of the Greater Antilles (Losos et al., 1998), and species within an
57 ecomorph exhibit coordinated combinations of adaptations to their structural microhabitat. For
58 example, trunk-ground species are generally medium-sized brown lizards with long limbs and a
59 stocky build, and as sit-and-wait predators they perch low on tree trunks and forage on the
60 ground and in low vegetation. Twig species, on the other hand, are mottled gray or brown, have
61 short limbs and narrow bodies, and move slowly and cryptically on small branches in the
62 canopy. There is a rich body of literature that compares a wide range of traits both among and

63 within the anole ecomorphs (reviewed in Losos, 2009), but the majority of studies focused on
64 within-ecomorph variation has focused on variation in traits not directly associated with anole
65 ecomorphology (e.g., thermal ecology: Ruibal, 1961, Rand, 1964, Hertz et al., 2013; body size:
66 Muñoz et al., 2014; but see Wollenberg et al., 2013). In this study, we examined variation in the
67 morphological, ecological, and behavioral traits that distinguish different ecomorphs within a
68 group of species of a single ecomorph: the Hispaniolan trunk-ground anoles.

69 The closely-related cybotoid anoles in Hispaniola have spread into different
70 macrohabitats across the Dominican Republic and Haiti; thus, this clade offers an ideal
71 opportunity to test ecomorphological hypotheses within an ecomorph (Glor et al., 2003;
72 Wollenberg et al., 2013). The group of cybotoid lizards includes *A. cybotes* (including *A.*
73 *armouri* and *A. shrevei*, which are nested within *A. cybotes*; Wollenberg et al., 2013), *A.*
74 *marcanoï*, *A. whitemani*, *A. longitibialis*, and *A. strahmi*. Here, we focus on three of these species
75 (Fig. 1): *A. cybotes*, a macrohabitat generalist that occurs throughout the island of Hispaniola; *A.*
76 *longitibialis*, a species restricted to rocky outcrops in the xeric southwestern Dominican Republic
77 (Gifford et al., 2003); and *A. marcanoï*, a species that occurs in south-central Dominican
78 Republic in semi-xeric to semi-mesic forest habitats (Glor et al., 2003). Using these three
79 species, we tested the hypothesis that ecological traits associated with morphological
80 differentiation *across* ecomorphs are also associated with morphological traits *within* an
81 ecomorph.

82 First, one of the defining traits of anole ecomorphs is based on the relationship between
83 limb morphology and perch diameter. Longer-limbed species (i.e., trunk-ground and trunk-crown
84 species) predominantly use larger perches and exhibit higher sprint speeds on broad perches than
85 shorter-limbed species (i.e., grass-bush and twig species; Losos, 1990; Irschick and Losos,

86 1999), while shorter limbs are generally associated with increased maneuverability on smaller
87 perches (Losos and Sinervo, 1989; Irschick and Losos, 1998). In addition, toepad morphology is
88 associated with clinging ability in anoles (Irschick et al., 1996), and the more arboreal anole
89 ecomorphs generally have larger subdigital toepads, with more adhesive lamellae, than the more
90 terrestrial ecomorphs (Glossip and Losos, 1997). Locomotor performance in anoles is also
91 dependent on substrate type (smooth or rough) and angle of incline, with lizards running faster
92 on rough substrates and larger males pausing or slipping more frequently on smooth, vertical
93 substrates (Kolbe et al., 2015). Further, anoles preferentially use perches that allow maximum
94 locomotor performance (Irschick and Losos, 1999, but see Kolbe et al., 2015). Based on these
95 previous findings, we tested three predictions regarding limb morphology, perch use, and
96 locomotor behavior. 1a) Species with longer limbs, larger toepads, and more lamellae on their
97 toepads will use broader perches. 1b) Longer limbed species will perform more fast locomotor
98 movements (i.e., runs and jumps), and shorter-limbed species will perform more slow
99 movements (i.e., crawls). 1c) The macrohabitat generalist species (*A. cybotes*) will exhibit more
100 variation in perch use, and thus locomotor behavior, than the two macrohabitat specialist species
101 (*A. longitibialis* and *A. marcanoii*).

102 Second, anole ecomorphs differ in the extent of sexual size dimorphism (SSD), with
103 trunk-ground and trunk-crown species exhibiting high male-biased SSD, and the other four
104 ecomorphs with low SSD (Butler et al., 2000). This variation in SSD has been attributed to both
105 ecological variation between the sexes and to intrasexual selection (Butler et al., 2000). Here, we
106 use SSD as a proxy for the strength of pre-copulatory sexual selection, following the extensive
107 empirical evidence that males in general, and particularly in lizards, evolve larger body sizes as
108 the result of competition for mates or other resources (Andersson, 1994; Cox et al., 2003, 2007).

109 We tested the hypothesis that SSD in cybotoid anoles was associated with sexually-selected
110 morphologies and behaviors, with the following predictions. 2a) Because intense male conflict in
111 anoles may escalate to locking jaws (e.g., Greenberg and Noble, 1944; Jenssen et al., 2000),
112 species with high SSD will exhibit relatively larger head dimensions, which offer stronger bite
113 forces (e.g., Herrel et al., 1999, 2001). 2b) Male anoles perform displays that include extensions
114 of the dewlap (a colorful throat fan), head-bobs, and push-ups in courtship and aggression
115 (Jenssen, 1977). Thus, we predicted that species with high SSD will have larger dewlaps and
116 more frequent dewlap and push-up display behaviors. 2c) Finally, because pre-copulatory male
117 competition may be associated with an energetic trade-off with post-copulatory sperm
118 competition (Preston et al., 2003; Fitzpatrick et al., 2012; Parker et al., 2013; Lüpold et al., 2014;
119 Kahrl et al., *in press*), species with high SSD will have smaller testes.

120

121 MATERIALS AND METHODS

122 ***Measures of Behavior and Habitat Use.***—We examined adult male anoles of the three focal
123 species in the Dominican Republic during the summer breeding season in 2005, 2009, 2010, and
124 2015. We studied *Anolis cybotes* at Coralsol Beach Resort in La Ciénaga, Barahona (N 18°
125 03'42.2", W -71° 06'39.9"); *Anolis longitibialis* in Manuel Goya (N 17° 50'8.5", W -71° 27'0.5"
126 and N 17° 48' 9.216", W -71° 26' 51.792"); and *Anolis marcanoi* near El Matadero (N 18°
127 23'10.0", W -70° 26'31.4"; N 18° 24' 9.936", W -70° 25' 12.792"; and N 18° 19' 30.18", W -
128 70° 17' 20.508"). We performed behavioral observations and morphological measurements in
129 2015, and recorded habitat use in each of the four years of study.

130 We conducted 12-120 min focal observations on adult males of each species (*Anolis*
131 *cybotes*: n = 43, 20.6 h observation; *Anolis longitibialis*: n = 31, 33.5 h observation; *Anolis*

132 *marcanoi*: n = 4, 6.5 h observation), as follows. We located undisturbed lizards by walking
133 slowly through the habitat, and then observed the behavior of the focal lizard using binoculars,
134 from a minimum distance of 5 m. During behavioral data collection, we recorded all display
135 behaviors (focusing on dewlap extension and head-bob and push-up displays), locomotor
136 movements (with each movement categorized as a run, crawl, or jump), and copulations. To
137 prevent repeated observations of the same male, we only observed lizards on perches separated
138 by a minimum of 10 m, and we systematically conducted observations in different areas of the
139 locality each day. All observations were performed between 0930 and 1730, and never in
140 inclement weather (i.e., rain). For each individual, we calculated rates of each display behavior
141 (dewlap extensions, combined head-bobs and push-ups) per min, the total rate of locomotor
142 movements per min, and the average duration of each dewlap extension in sec. We also
143 determined the proportion of movements of each locomotor type (runs, crawls, and jumps) and
144 the proportion of “fast” (runs or jumps) and “slow” (crawl) movements for each individual.

145 To obtain measures of habitat use, we noted the type of substrate on which each
146 individual perched during behavioral observations. Perch diameter was collected for lizards that
147 were seen before they were disturbed, and never for lizards that were first seen moving.

148 Additionally, we recorded the orientation of the lizard on the perch as quasi-horizontal (0° - 30°)
149 or quasi-vertical (31° - 90°).

150

151 ***Morphological Measurements.***—To collect morphological measurements, we captured 7-17
152 adult males of each species by hand or noose. (These males were always not the same males on
153 which behavioral observations were performed and perch data were collected.) We measured the
154 snout-vent length (SVL) of each lizard to the nearest mm using a plastic ruler or digital calipers

155 to the nearest 0.01 mm. We also captured 11-26 adult females of each species from the same
156 localities, and measured their SVL to obtain measures of SSD. We calculated the average male
157 and female SVL for each species, and calculated the SSD of each species as:

$$SSD = \frac{Male\ SVL}{Female\ SVL} - 1$$

158 following Lovich and Gibbins (1992). If males are larger than females, then by convention this
159 measure of SSD is positive.

160 For adult males, we measured a series of additional morphological traits. Mass was
161 measured to the nearest 0.1 g using a Pesola spring scale, and external head and limb dimensions
162 were each measured to the nearest 0.1 mm using digital calipers. Head length was measured as
163 the distance from the parietal eye to the tip of the snout, head width was measured at the widest
164 part of the skull (the anterior base of the cranium), and head depth was measured at the deepest
165 part of the skull (immediately behind the eyes). We measured the femur length as the distance
166 between the body wall and the most distal point of the knee, tibia length as the distance between
167 the knee and the most distal point of the foot, and fourth toe length as the distance between the
168 tip of the longest toe (metatarsal IV) not including the claw, and the point of insertion of the toe
169 at the footpad. Three characteristics of the subdigital toepad on the fourth toe were also
170 measured: number of lamellae on the toepad, pad length, and pad width. These traits were
171 measured using digital flatbed scans with a resolution of 2400-3200 dpi, and were analyzed with
172 the software Image J (NIH, Bethesda). All foot measurements were taken twice, and we used the
173 mean of these measures in subsequent analyses (modified after Zani, 2000). We measured the
174 hindlimb, fourth toe, and toepad on the right side of the lizard unless it was injured, in which
175 case we measured the left side.

176 To measure dewlap size, we held the lizard's head parallel to a background of white
177 graph paper and photographed the dewlap, fully extended using forceps, twice for each animal.
178 We measured the area of both photographs of each dewlap using ImageJ (NIH), and then used
179 the larger of the two measures in subsequent analyses.

180 Because these animals were also used in a series of other physiological studies, a subset
181 of lizards on which morphological measurements were made were transported to Trinity
182 University and euthanized by rapid decapitation. Immediately following euthanasia, we opened
183 the body cavity and measured the length and width of the right testis, before the testis was
184 removed from the animal. These measures were used to calculate testis volume using the formula
185 for the volume of an ellipsoid ($4/3\pi a^2 b$), where a is the radius of the width of the testis and b is
186 the radius of its length. We converted this measure of testis volume to a measure of mass using
187 the density of testis tissue ($1\text{mm}^3/\text{mg}$) reported by Licht and Pearson (1969). We then calculated
188 gonadosomatic index (GSI, the ratio of testis mass to body mass) for each individual.

189
190 ***Statistical Analysis.***—We conducted all statistical analyses in JMP (version 9.0, 2010; SAS
191 Institute Inc., Cary, NC). All morphological traits were \log_{10} transformed for our analyses. As
192 head measurements are highly correlated, we used Principal Component Analysis (PCA) to
193 summarize \log_{10} head length, \log_{10} head width and \log_{10} head depth. This returned one significant
194 PC ($\chi^2 = 135.34$, $df = 5$, $P < 0.001$) that explained 92.6% of the variance and had positive
195 loadings of head length (0.95), depth (0.96), and width (0.97). We interpreted this PC as an
196 overall measure of head size, and included this as Head Size PC in subsequent analyses.

197 To test for differences among species in body shape, we used body-sized corrected
198 residuals from the regression of the \log_{10} transformed trait on \log_{10} SVL, which included all

199 individuals of all species. We then used a series of analyses of variance (ANOVA) to test for
200 differences among the three species in \log_{10} SVL, Head Size PC, GSI, number of lamellae on the
201 fourth toepad, and the residuals of mass, head length, head width, head depth, femur length, tibia
202 length, fourth toe length, fourth toepad length and width, and dewlap size. We used Tukey's
203 HSD post-hoc tests for all pair-wise comparisons following significant ANOVA results.

204 To test for differences among species in rates of behavioral traits (dewlap extension,
205 head-bobs and pushups, total movements), proportion of type of locomotor movements (runs,
206 crawls, or jumps), and fast (runs and jumps) and slow (crawls) movements, and the average
207 duration of dewlap extension among the species, we again used a series of ANOVA. Copulation
208 was rarely observed during these observations, and thus could not be statistically analyzed. We
209 used a series of Brown-Forsythe tests to assess the equality of variance in behavioral traits
210 among the species. We also tested for differences in substrate use and substrate orientation
211 (horizontal or vertical) between species using chi-square tests. Because our data on perch
212 diameter for *A. longitibialis* was very limited, *A. longitibialis* was removed from the analysis of
213 diameter. We then compared differences in perch diameter between *A. cybotes* and *A. marcanoi*
214 using ANOVA.

215

216 **RESULTS**

217 Morphological analysis showed that the three cybotoid species differed significantly in body size
218 and limb dimensions (Table 1, Fig. 2, Supplemental Table 1). *Anolis cybotes* and *A. longitibialis*
219 did not differ in SVL, but *A. cybotes* had the largest relative mass, while *A. marcanoi* was the
220 smallest species in both measures of overall size. We also found that *A. longitibialis* had
221 significantly longer hindlimbs and shorter fourth toes with fewer lamellae than *A. cybotes* and *A.*

222 *marcanoii*, and *A. cybotes* had shorter hindlimbs, longer toes, and more lamellae than the other
223 species (Table 1, Fig. 2).

224 We also found that the three species differed in locomotor behavior and perch type (Fig.
225 3, Supplemental Table 2). *Anolis cybotes* moved substantially more frequently than *A.*
226 *longitibialis* ($F_{2,49} = 6.23$, $P = 0.003$, Fig. 3), and had a higher variation in the frequency of their
227 movements ($F_{2,75} = 6.83$, $P = 0.001$). However, the proportion of each type of movement (runs,
228 crawls, and jumps) did not differ among the three species (all $P > 0.17$; Fig. 3) nor did the
229 proportion of fast movements (runs, and jumps) ($F_{2,69} = 0.10$, $P = 0.25$), or slow movements
230 ($F_{2,69} = 2.38$, $P = 0.10$). We also did not find a significant difference in the variance of each of
231 these types of movements (all $P > 0.18$).

232 Further, perch use differed substantially among the species ($\chi_2 = 122.9$, $df = 10$, $P <$
233 0.001), such that *A. longitibialis*, the species with the longest limbs and shortest toes and the
234 fewest lamellae on their fourth toepads, was most often found on rocks, while *A. marcanoii* was
235 most often found on fence posts and tree trunks. *Anolis cybotes* occupied the widest range of
236 habitats, but was predominantly found on tree trunks and branches (Fig. 3), and was found on
237 vertical branches more often than *A. marcanoii* and *A. longitibialis* ($\chi_2 = 13.05$, $df = 2$, $P = 0.001$).
238 We found marginally significant differences in perch diameter between *A. cybotes* and *A.*
239 *marcanoii* ($F_{1,26} = 3.06$, $P = 0.092$), where *A. cybotes* inhabited perches that were slightly
240 narrower than *A. marcanoii*.

241 The three species also differed in the extent of SSD, with *A. longitibialis* (SSD = 0.352)
242 exhibiting the most dimorphism, followed by *A. cybotes* (SSD = 0.169), and *A. marcanoii* (SSD =
243 0.085). Consistent with our predictions, the species with lowest SSD (*A. marcanoii*) had the
244 smallest head (Head Size PC), but contrary to expectation, it exhibited the largest relative dewlap

245 (Table 1, Fig. 4D). Despite significant differences in the Head Size PC, the three species did not
246 differ in head shape, as measured by the relative head length, width, and depth (Table 1).
247 Further, our prediction that other morphological and behavioral traits associated with
248 precopulatory sexual selection would be positively associated with the extent of SSD was not
249 supported. *Anolis cybotes*, the species with intermediate SSD, performed a higher rate of dewlap
250 extensions (Fig. 4E, $F_{2,77} = 12.20$, $P < 0.001$) and head-bobs/pushups (Fig. 4C, $F_{2,77} = 13.31$, $P <$
251 0.001) than *A. longitibialis*, although the species did not differ in the average duration of dewlap
252 extension (Fig. 4F, $F_{2,59} = 2.18$, $P = 0.122$). The species also differed in testis morphology in the
253 direction we predicted: the least dimorphic species (*A. marcanoii*) had a higher GSI than the two
254 more dimorphic species (Fig. 4B, $F_{2,49} = 6.23$, $P = 0.003$).

255

256 DISCUSSION

257 Caribbean anoles are a classic example of adaptive radiation via niche partitioning, as ecomorphs
258 have evolved to occupy a wide range of microhabitats (Williams, 1983; Losos, 2009). Yet even
259 within the ecomorph groups, several clades have undergone further diversification within their
260 particular microhabitat on a given island. Among the best-studied examples of intra-ecomorph
261 diversification are the *Anolis sagrei* species group (Knouft et al., 2006), the cybotoid anoles
262 (Glor et al., 2003; Wollenberg et al., 2013), and the *Anolis carolinensis* species group (Burnell
263 and Hedges, 1990; Glor et al., 2004). These groups provide an ideal opportunity to study local
264 adaptation and speciation within a clade. Here, we demonstrate significant differences in the
265 morphology, ecology, and behavior of three species of closely-related cybotoid anoles.
266 Consistent with our predictions, we show an association between substrate use, morphology and
267 behavior, suggesting that each species of anole has experienced local adaptation to the variable

268 environments in the Dominican Republic. This pattern of adaptation mimics some patterns
269 among anole ecomorphs, where species with larger perches tend to have longer limbs (Losos and
270 Sinervo, 1989; Losos, 1990), but not others, as cybotoid species with longer limbs did not jump
271 and run more often than crawl, as shown across ecomorphs (Losos, 1990). Our data also suggest
272 that monomorphic species tend to have smaller heads and larger testes, consistent with theory on
273 sexually selected traits in this group (Kahrl et al., *in press*). However, we found no relationship
274 with dimorphism and social display behaviors. We explore these findings in more detail below.

275 Cybotoid anoles are a morphologically diverse group that inhabits a range of perch
276 substrates and macrohabitats in the Dominican Republic (Glor et al., 2003; Wollenberg et al.,
277 2013). We found that variation in microhabitat or substrate use has likely led to predictable
278 changes in their morphology and behavior, similar to the patterns of ecomorphological
279 divergence across Caribbean anoles (Losos and Sinervo, 1989; Losos, 1990). For these three
280 species, we found an association between the use of narrower perches, shorter hindlimbs, and
281 longer fourth toes with more lamellae on the toepad (Fig. 2, 3). This result mirrors patterns of
282 adaption among species across ecomorphs, where species that live on smaller perches tend to
283 have shorter limbs and with more lamellae, traits thought to aid in clinging ability while running
284 on small perches (Cartmill, 1985; Pounds; 1988; Losos, 1990). It also corroborates weak
285 associations between morphology and habitat previously described in this group (Glor et al.,
286 2003; Wollenberg et al., 2013). In particular, *A. cybotes* was observed on small vertical perches
287 most frequently, and had the shortest limbs, longest fourth toes, and most toepad lamellae of the
288 three species. Together, these traits suggest that this species has likely adapted to climbing and
289 running on narrow perches (Irschick et al., 1996; Zani 2000). On the other hand, *A. longitibialis*

290 likely has adapted to its saxicolous habitat with longer limbs that may enable this species to run
291 faster and jump farther on broad rocky surfaces (Losos, 1990; Irschick and Losos, 1999).

292 Yet contrary to our hypothesis, there was no difference in the proportion of fast or slow
293 movements between species of anoles. We did find, however, that the long-limbed saxicolous
294 species (*A. longitibialis*) tended to move less frequently than short-limbed arboreal species (*A.*
295 *cybotes*). Again, this relationship between microhabitat use and movement rate mimics a pattern
296 observed among broader groups of anoles, where species that live on tree trunks or branches tend
297 to have higher movement rates than those that live near or on the ground (Johnson et al., 2008).
298 This variation in movement rate may be due to differences in foraging behavior among species,
299 associated with variation in visibility from the lizard's perch (Johnson et al., 2008). In particular,
300 microhabitats with a greater density of twigs and branches tend to obscure visibility, and lizards
301 may move more frequently to survey the areas around them for prey or conspecifics (Moermond,
302 1979).

303 We also tested the hypothesis that generalist species, who use more diverse substrates,
304 exhibit higher variation in their locomotor behavior. *Anolis cybotes* used the widest variety of
305 substrates, while both *A. marcanoii* and *A. longitibialis* were observed on fewer substrate types,
306 and on a single substrate type > 60% of the time (Fig. 3A). This difference in perch use may be a
307 function of species-specific preferences for particular perches, perch availability, or an
308 interaction of the two (Johnson et al., 2006). Consistent with our hypothesis, we also found that
309 individual *A. cybotes* had higher variation in their overall movement rate than the other two
310 species. Since *A. cybotes* occupies more diverse perch types, there may be higher variation in
311 visibility and therefore, high variation in movement rates in this species (Moermond, 1979).

312 We measured several traits associated with pre- and postcopulatory selection in each of
313 these three species to test for associations between the strength of sexual selection, morphology,
314 and social behavior. These species vary in the extent of male-biased sexual size dimorphism
315 (Fig. 4), which can result from precopulatory selection on male body size (Cox et al., 2003,
316 2007). We predicted that species that experience strong precopulatory selection (i.e., high SSD),
317 would also have larger heads, and especially deeper and wider heads due to the use of the head
318 for biting during male-male combat (Lailvaux et al., 2004; Lailvaux and Irschick, 2007). We
319 found that the species with medium and high SSD (*A. longitibialis* and *A. cybotes*) had
320 significantly larger heads (Head Size PC), than the species with low SSD, *A. marcanoi* (Fig. 4A).
321 However, it is also possible that these species differ in head dimensions because of ecological
322 factors such as the size of the prey available in each habitat (Roughgarden and Fuentes, 1977).

323 We also predicted that species with strong precopulatory selection would exhibit larger
324 dewlaps and higher display rates, but we found that as SSD increased, dewlap area decreased,
325 and there was no association between SSD and dewlap rate in these species (Fig. 4). There have
326 been a variety of hypotheses proposed to explain variation in dewlap size and patterning among
327 species of anoles, many of which have found weak or non-significant support for differences
328 among ecomorph groups or for variation due to species recognition (Nicholson et al., 2007). Yet,
329 Williams and Rand (1977) found that among islands, populations that contained few species of
330 anoles did not differ in their dewlaps when other cues for species recognition were present (i.e.,
331 strong differences in other phenotypes). However, in populations where other cues were lacking,
332 anoles tended to have more variable dewlap colors (William and Rand, 1977). Among the three
333 species in this study, *A. marcanoi* has a reddish pink dewlap, while both *A. cybotes* and *A.*
334 *longitibialis* have pale yellow or white dewlaps. As *A. cybotes* and *A. marcanoi* have slightly

335 overlapping geographical ranges, the observed differences in color and size of the dewlap may
336 aid in species recognition, especially given the physical similarities between these two species.
337 Additionally, dewlap size is weakly associated with habitat illumination, which may also be
338 important in driving the evolution of the dewlap (Losos and Chu, 1998; Leal and Fleishman,
339 2004), although that was not a focus of the present study.

340 Finally, we observed that species with stronger precopulatory selection (SSD) had a
341 smaller GSI (Fig. 4B). This pattern was consistent with our predictions of a trade-off between
342 pre- and postcopulatory selection, and mirrors a trade-off that exists among other species of
343 anoles (Lailvaux et al., 2004; Lailvaux and Irschick, 2007; Kahrl et al., *in press*). This suggests
344 that the patterns of diversification in morphology due to sexual selection that occurs among
345 species across ecomorphs are also occurring within ecomorph groups.

346 Our current results may inform patterns of divergence among other groups of sympatric
347 and allopatric anole species within the same ecomorph in Cuba and Hispaniola that exhibit niche
348 partitioning (Losos et al., 2003; Glor et al., 2004; Knouft et al., 2006) similar to the patterns
349 observed among ecomorphs on each island (Williams, 1983; Losos, 1990; Losos et al., 1998). In
350 particular, the cybotoid group of anoles show significant differences in their morphology that is
351 independent of their phylogenetic relationships (Glor et al., 2003), and can be attributed to a
352 combination of microhabitat and genetic differentiation between these species (Wollenberg et al.,
353 2013). Here, we found that the closely related species *A. cybotes*, *A. longitibialis*, and *A.*
354 *marcanoi* exhibited striking differences in their morphology, ecology, and behavior that are
355 likely due to local adaptation to varying macro- and microhabitats and differences in the strength
356 of sexual selection among species. In sum, ecomorphological variation can indeed produce
357 divergence both among and within anole ecomorphs.

358

359 **ACKNOWLEDGEMENTS**

360 We thank F. Deckard, M. Jaramillo, M. Webber, A. Zeb, M. Landestoy, and C. Marte for their
361 assistance in field data collection during this study, and L. Selznick and J. Stercula for laboratory
362 support. We would also like to thank the people of Manuel Goya and the staff of Coralsol Beach
363 Resort for their hospitality and logistical support. This study was conducted under permission
364 from the Ministerio de Medio Ambiente y Recursos Naturales of the Dominican Republic. This
365 work was funded in by the National Science Foundation (NSF IOS 1257021 to MAJ), the E.E.
366 Williams Research Grant from the Herpetologist's League (to AFK), and a Doctoral Dissertation
367 Improvement Grant from the National Science Foundation (DEB-1501680 to RMC and AFK).
